Group Coursework Submission Form

Specialist Masters Programme

Please list all names of group members: (Surname, first name) Delalande, Paul Nguyen, Ngoc Minh Khue Doan, Tien Thanh	Rota, Pietro **GROUP NUMBER:** **8**
MSc in: Banking and International finance	
Module Code: SMM149	
Module Title: Fixed Income	
Lecturer: Xiao Han	**Submission Date:** 20/03/2026

Declaration:

By submitting this work, we declare that this work is entirely our own except those parts duly identified and referenced in my submission. It complies with any specified word limits and the requirements and regulations detailed in the coursework instructions and any other relevant programme and module documentation. In submitting this work we acknowledge that we have read and understood the regulations and code regarding academic misconduct, including that relating to plagiarism, as specified in the Programme Handbook. We also acknowledge that this work will be subject to a variety of checks for academic misconduct.

We acknowledge that work submitted late without a granted extension will be subject to penalties, as outlined in the Programme Handbook. Penalties will be applied for a maximum of five days lateness, after which a mark of zero will be awarded.

Marker's Comments (if not being marked on-line):

Deduction for Late Submission of assignment:

For Students:
Once marked please refer to Moodle for your final coursework grade, including your Peer Assessment grade.

Introduction

This report analyses the term structure of interest rates and credit risk in the Japanese fixed income market through a comparison of Japanese Government Bonds (JGBs) and Toyota corporate bonds. Using market prices, the study first computes dirty prices and coupon cash flows, then estimates the corresponding spot rate and forward rate curves for both the sovereign and corporate bond sets. The comparison between these curves will allow us to identify the implied forward credit spread and assess how investors price time value, liquidity, and credit risk across maturities.

Bond selection

For this report we decided to tackle Japanese government bonds and Toyota corporate bonds, this paring a strong setting for bond structure and forward rates comparison. On one side we have Japan, which has an unconventional sovereign bond market structure, due to its decade of macroeconomic doctrine driven by an anti-deflation policy, ultra-low interest rates, large scale asset purchases and yield curve control, all of which distorted and compressed the Japan Government Bond curve relative to other sovereign bond market. That makes Japan an analytically interesting subject for this paper, especially since now the Bank of Japan decided to exit its earlier framework by ending negative interest rates and curve control in 2024. On the other side there is Toyota, the world's best-selling car company in the world in 2025, also a high-grade borrower with strong credit rating and global market access. This makes Toyota bonds suitable for extracting corporate curves, as the issuer is credit sensitive enough to generate a measurable spread over government bonds, but at the same time financially strong enough that the spread reflects priced credit and liquidity risk.

Data collection

For this paper, all data was directly collected from Bloomberg, on the 10th of March 2026. All the bonds used for this report were high quality, fixed coupon vanilla bonds with maturities ranging from a couple

of weeks to 40 years, all data was gathered from Bloomberg totalling 326 government bonds and 37 corporate bonds.

We were able to calculate the Accrued Interest by downloading also the date of the last coupon issued in the dataset and taking the convention 30/360.

Methodology

We chose to use the Nelson-Siegel-Svensson (NSS) model. This model, through its parameters, captures the level, slope, and curvature of the yield curve, allowing us to be able to derive smooth spot and forward rate curves from the observed bonds. The simplified Nelson-Siegel version of the model lacked the complexity needed to capture accurately the yield curve, so we opted to use the amplified NSS model.

$$r(t) = \beta_0 + \beta_1 \frac{1 - e^{-\frac{t}{\tau 1}}}{\frac{t}{\tau 1}} + \beta_2 \left(\frac{1 - e^{-\frac{t}{\tau 1}}}{\frac{t}{\tau 1}} - e^{-\frac{t}{\tau 1}} \right) + \beta_3 \left(\frac{1 - e^{-\frac{t}{\tau 2}}}{\frac{t}{\tau 2}} - e^{-\frac{t}{\tau 2}} \right)$$

From there this spot rate we can get the forward rate as well by reversing their relationship

$$(1 + r_{t2})^{t_2} = (1 + r_{t1})^{t_1} \times \left(1 + f_{t_1,t_2}\right)^{t_2 - t_1}$$

$$f_{t_1,t_2} = \left[\frac{(1 + r_{t2})^{t2}}{(1 + r_{t1})^{t1}}\right]^{\frac{1}{t2 - t1}} - 1 \quad \rightarrow \quad f_{t_1,t_2} = \frac{(1 + r_{t1})^{-t1}}{(1 + r_{t2})^{-t2}} - 1$$

The best fit was achieved by minimizing the root mean square error (RMSE) of the yield, rather than the mean absolute error (MAE).

A possible explanation for obtaining better results when minimizing RMSE rather than using the MAE in the as the objective function may lie in the different ways these loss functions penalize errors. RMSE uses squares deviations, thereby assigning larger weight to large errors, while MAE treats all deviations linearly. In the context of yield curve estimation, certain maturities, especially the longer maturities and

the bonds that are not as liquid, which are more often difficult to fit. By penalizing large deviations more heavily, RMSE forces the model to closely match these critical regions, leading to a more stable and economically meaningful parameter estimation. This feature is particularly important for estimating the curvature and decay components of the NSS specification. RMSE tends to produce smoother and more globally consistent yield curves, which better capture the underlying term structure dynamics.

Model Parameters

Parameter	Value
β_0	5.64%
β_1	−4.22%
β_2	−4.23%
β_3	0.58%
τ_1	4.72
τ_2	0.60

Model Fit Metrics

Metric	Value
MAE (Price)	0.3426
MAE (Yield)	660
RMSE (Price)	0.4604
RMSE (Yield)	1017

Results

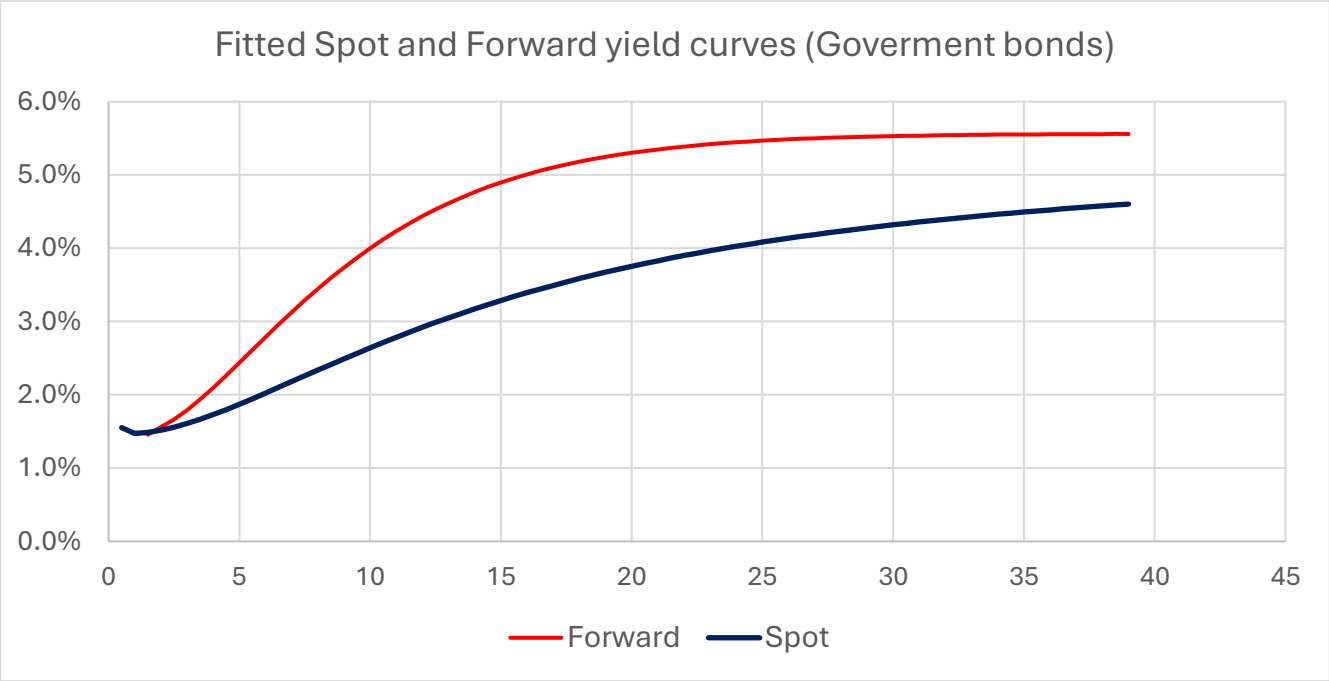

Figure 1: Fitted spot and forward yield curve for JGBs

Figure 1 shows that the spot curve is upward sloping across the whole maturity range, with the spot rate increasing from 1.55% at 0.5 years to 1.87% at 5 years, 2.64% at 10 years, 3.75% at 20 years, and 4.31% at 30 years, before rising further to 4.58% at the long end. This suggests that yields increase steadily with maturity rather than showing a strong hump or inversion.

The forward curve is steeper than the spot curve. Implied forward rates are above spot rates in the medium term and continue to rise across the maturity range. They are around 2.42% at 5 years, 4.02% at 10 years, 5.28% at 20 years and 5.48% at 30 years. This indicates that the market is pricing higher future borrowing and lending rates than current rates on the same horizon. The forward curve therefore implies that the compensation for lending in later periods increases with maturity.

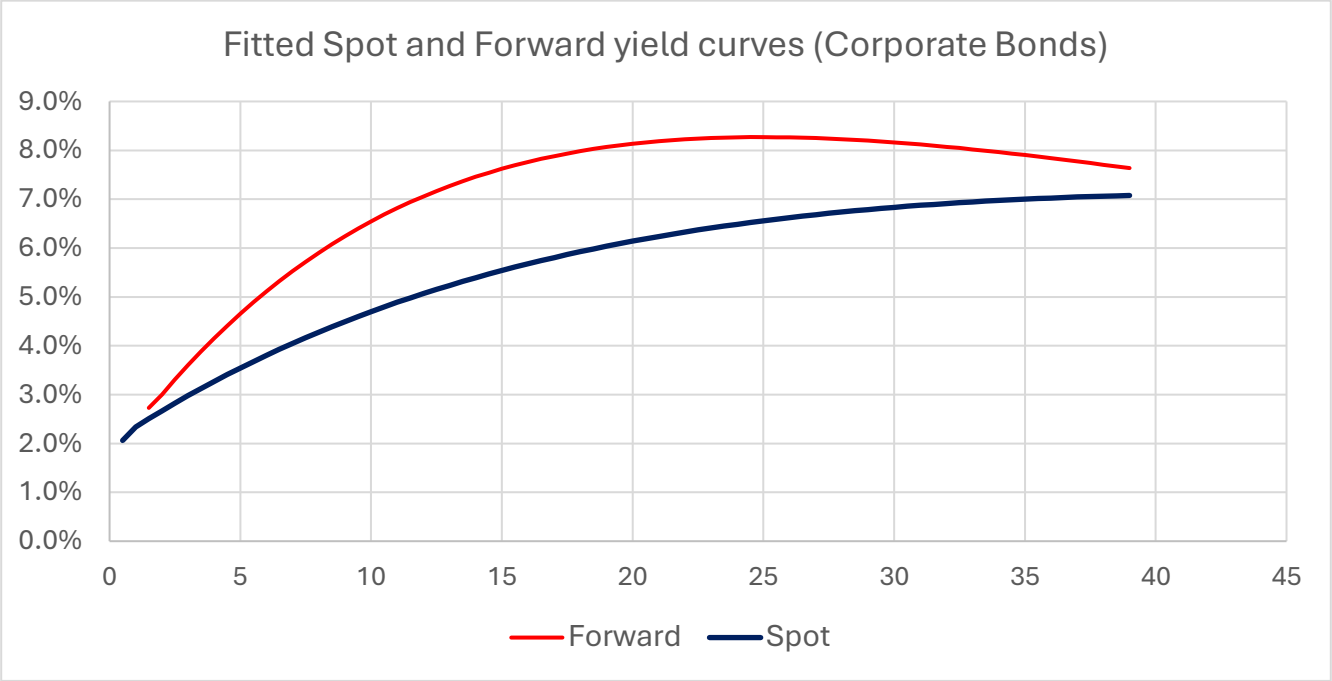

Figure 2: Fitted spot and forward yield curve for Toyota Bonds

Figure 2 shows that the corporate spot curve is upward sloping across the whole maturity range, with the spot rate increasing from 2.05% at 0.5 years to 3.56% at 5 years, 4.71% at 10 years, 6.16% at 20 years, and 6.84% at 30 years, before reaching approximately 7.08% at the long end. This suggests a steady increase in yields with maturity, reflecting the higher credit and liquidity risk premiums associated with Toyota's corporate debt compared to government securities.

The forward curve is notably steeper than the spot curve in the medium term and exhibits a distinct humped shape. Forward rates rise sharply to around 4.67% in 5 years, 6.53% in 10 years, and 8.08% in 20 years, peaking near 8.28% at the 25-year mark before gradually declining to 7.64% in the long end. This indicates that the market is pricing significantly higher future borrowing costs in the medium term, while the slight inversion at the ultra-long end suggests a marginal decrease in the expected compensation for lending in later periods.

Both of these examples highlight the strength of the NSS model in filtering out the noise often found in corporate bond data due to varying credit qualities and lower liquidity, as well as bid-ask spreads, and issue-specific distortions in the government case. The model fit appears reasonable and provides a

smooth, monotonic spot curve and forward rates and valuing private cash flows across the maturity spectrum.

While bootstrapping would fit each bond exactly but might generate noisy yield curves. The model fit is reasonable rather than exact. The low fit metrics indicate that the fitted curve captures the cross-section of bond prices well. Some residual error is expected, and it actually reinforces the economic conditions rather than chasing the perfect fit.

Model Accuracy and Realism

The Nelson-Siegel-Svensson model's performance in the analysis ended with reasonable results since it has been able to extract the underlying pattern of the term structure from the bond prices without being affected by local noise in the bond prices. This further indicates the strength of the design in the analysis context where the prices for both government and corporate instruments can be potentially influenced by not only simple discounting of cash flows but also liquidity conditions, bid-ask spreads, credit quality, and issue-specific distortions. Furthermore, another key advantage of the model is its ability to impose a smooth and coherent functional form on the data, allowing the curves to reflect the primary pricing structure rather than irregularities in individual bonds. In such context, the efficiency of the NSS model should not be judged by its capabilities to match every bond price exactly but by how efficient the derived term structure remains consistent with the principal bond prices.

From a realism perspective, the fitted curves should be viewed as robust summary of the markets instead of a precise fit to a frictionless "correct" yield curve. This is essential because approach like bootstrapping could fit each bond perfectly, but it can produce unstable or noisy components that are not economically relevant. On the other hand, the NSS framework allows small residual errors in return for a better curve that is smooth, stable, and have better economic interpretation. Also, it should be noted that errors in any curve fit may not just a flaw but a necessary part of realism due to their role as observation of market frictions as well as fundamental pricing information. This approach to modelling should be viewed as

most reasonable in terms of identifying term structure features and pricing relationships in aggregate rather than a precise tool for bond-by-bond valuation in the market.

Forward credit spread

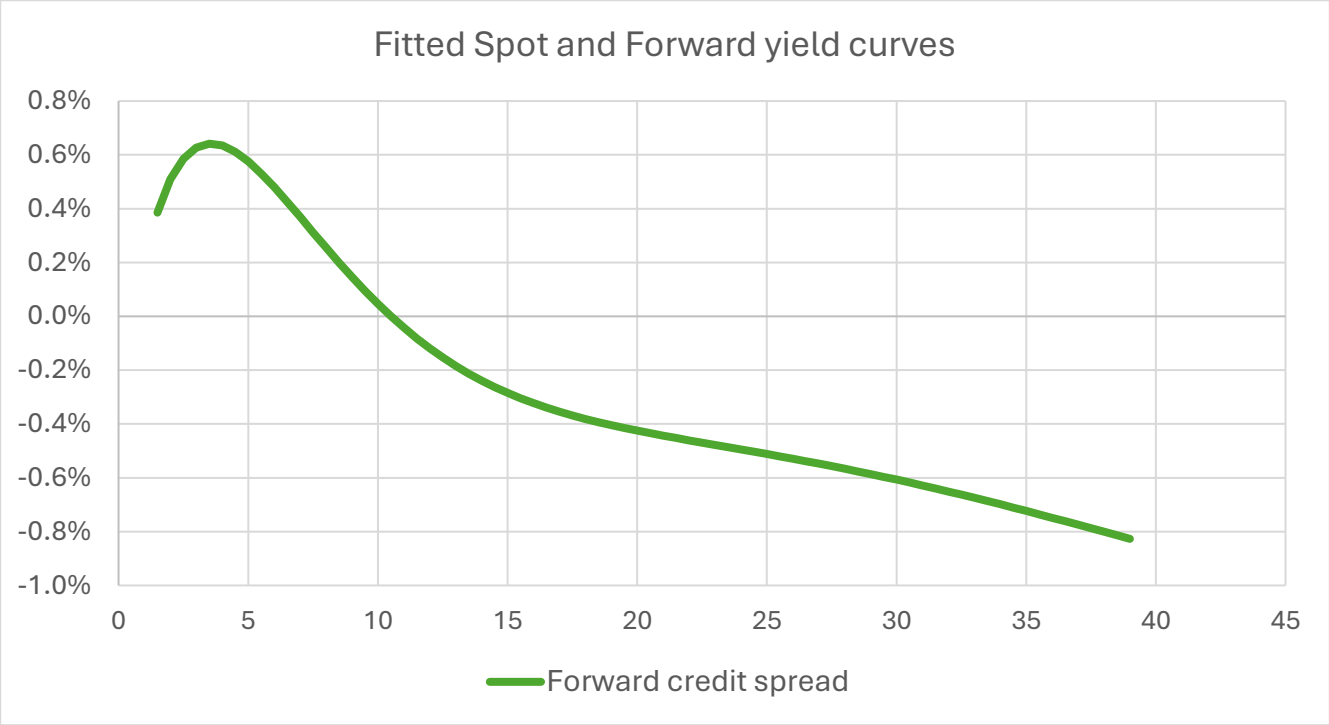

Figure 3: Forward credit spread (Toyota forward rate minus JGB forward rate)

Figure 2 shows that the Toyota minus JGB credit spread is slightly positive at the very short end, at just above 0.6%, but then falls sharply into the negative after roughly the 10-year horizon and stabilizes near –0.8% at longer maturities. The positive spread at the short end can be economically explained by the fact that Toyota is a very strong borrower, with high-grade long-term bonds. When looking at the curve literally, it could imply that Toyota forward rates are below the JGBs forward rates, but this is unlikely reflecting a true negative credit premium. A more explanatory response is that the curve reflects a combination of Japan specific sovereign market distortion and forward rate estimation sensitivity. The bank of Japan has explicitly acknowledged that its QQE (Quantitative and Qualitative Monetary Easing) and Yield curve control framework reduced JGB market liquidity and distorted relative prices, while BOJ

research also finds that JGB yield-curve distortion increased materially in 2022–2023 and affected the pricing environment for Japanese corporate bonds as well. In addition, when using a model such as the NSS, forward curves are highly model-dependent; ECB studies tell us that forward curves can differ substantially across estimation methods, are constrained to flatten at the long end, and may change sharply when even a single long-maturity data point moves. Therefore, the graph tells us on the front end that Toyota trades with a sensible positive premium, but the deeply negative long end is more likely to reflect fitted-curve and benchmark distortions than a true negative credit-risk premium.

Conclusion

In conclusion this report used the NSS model to estimate the spot and forward rate curve for Japanese sovereign bonds and Toyota corporate bonds, to analyse the term structure as well as the implied forward credit spread. The findings show that both issuers display upward-sloping spot curves, suggesting a positive corporate premium at shorter maturities. However, the negative long-end forward credit spread is less robust as an indicator of credit risk and should be treated cautiously. This trend is most likely due to the influence of the estimation sensitivity and distortion in the JGB market. Overall, the analysis suggests that the use of the NSS is a good approach to summarize market pricing, but long horizon forward credit spread should be interpreted with caution.
